Abstract: A 3-month (June–August) regime of the year 2002 summer rainfall (JJA2002) was simulated with 30 physics combinations using the Weather Research and Forecasting (WRF) model at 12-km horizontal grid resolution. The objective is to examine summer rainfall sensitivity to parameterization of microphysical, convective, and boundary layer processes and identify an best possible combination of parameterization options that performs relatively better in simulating spatial and temporal distribution of summer rains over Ethiopia. The WRF simulated rainfall was evaluated against station data and satellite rainfall products (CHIRPS and ENACTS) using mean absolute error, Pearson and Pattern correlation coefficients (PCC), pattern correlation and and error in number of rainy days as evaluation metrics. Summer rainfall is found to be most sensitive to choice of cumulus parameterization and least sensitive to cloud microphysics. All simulations captured the spatial distribution of mean seasonal precipitation with PCC ranging from 0.89–0.94. However, all simulations overestimated precipitation amount and number of rainy days. Out of the 30, the simulations that uses a combination of Grell-3D cumulus scheme, ACM2 boundary layer, Lin Microphysics, Dudhai shortwave radiation and RRTM longwave radiation scheme ranked the top and provided the most realistic simulation in terms of amount and spatio-temporal distribution of summer rainfall.

1. Introduction

Advancements in scientific understanding of the climate system and climate modeling have promoted seasonal forecasting to be a well-established operational area at several national centers [1]. As a result, different centres around the world (e.g., the National Center for Environmental Prediction-NCEP, the European Center for Medium Range Weather Forecast-ECMWF, Australian Bureau of Meteorology) run seasonal forecasting systems (e.g., the Climate Forecast System version 2 [CFSV2, 2], seasonal forecast system [SEAS5, 3], and the Australian Ocean-Atmosphere Model for Climate Prediction [POAMA, 4] respectively on a global scale. These seasonal forecast products provide reasonable global perspectives and outlooks of the climate several months in advance. However, despite their potential applications for different socio-economic sectors, the usefulness of these forecasts has been limited because of their coarse spatial resolutions [1,5]. In order for such climate forecasts to be of practical societal value, it is essential for them to be issued at spatial scales appropriate to the decision maker or at the scale needed to exploit them further (e.g., using them as an input for hydrologic or crop simulation models) [5]. To address the scale problem and meet the need for regional information, downscaling seasonal forecast by using regional climate models (RCMs) became an emerging area during the last decade [5–7].

Several studies around the world have demonstrated the potential advantages of using RCMs to downscale coarse resolution climate predictions [e.g., 1,8–15]. Although

It was by [New Permafrost and Glacier Research](#) Max I. Krugger, 2009. In geology, permafrost or permafrost soil is soil at or below the freezing point of water (0°C or 32°F) for two or more years. Ice is not always present as may be in the case of nonporous bedrock but it frequently occurs and it may be in amounts exceeding the potential hydraulic saturation of the ground material. Most permafrost is located in high latitudes, i.e., land in close proximity to the North and South poles but alpine permafrost may exist at high altitudes in much lower latitudes. The extent of permafrost can vary as the climate changes. Today approximately 20% of the Earth's land mass is covered by permafrost including discontinuous permafrost or glacial ice. A glacier is a large, slow-moving mass of ice formed from compacted layers of snow that slowly deforms and flows in response to gravity and high pressure. The word glacier comes from French via the Vulgar Latin *glacia* and ultimately from Latin *glacies* meaning ice. Glacier ice is the largest reservoir of fresh water on Earth and second only to oceans as the largest reservoir of total water. Glaciers cover vast areas of polar regions and are found in mountain ranges of every continent and are restricted to the highest mountains in the tropics. The processes and landforms caused by glaciers and related to them are referred to as glacial. The process of glacier growth and establishment is called glaciation. Glaciers are sensitive monitors of climate conditions and are crucial to both world water resources and sea level variation. This book presents the latest research on both permafrost and glaciers.

The Sensitivity of Tropical Cyclone Simulations in the WRF Model to Surface Layer and Planetary Boundary Layer Parameterization, 2003. The high wind speeds found in tropical cyclones fundamentally change the physical processes by which heat, moisture, and momentum are transferred between the ocean and the lower atmosphere. Despite this fact, surface and boundary layer parameterization schemes in many numerical models that are frequently used for tropical cyclone simulations are based on assumptions made in more tranquil atmospheric conditions. Limited observations in the high wind speed conditions found in strong tropical cyclones suggest that spray and foam can enhance the transfer of heat and moisture from the ocean to the atmosphere while reducing drag. Inclusion of the effects due to sea spray in a numerical model leads to stronger tropical cyclones. Wang et al. (2001), Perrie et al. (2005). Based upon the absence of sea spray effects and the values of the exchange coefficients in the WRF model, it was anticipated that simulations using an idealized vortex and ambient environment would not reach the thermodynamically estimated theoretical maximum intensity (MPI) limit of Emanuel (1986). In addition, it was expected that simulations of Hurricane Ivan would not reach the intensity of the observed storm. The sensitivity of the model results to surface layer and PBL parameterization and model grid spacing was tested with the hypothesis that the simulated tropical cyclones would remain weaker than MPI theory for the idealized simulations or observations for the Hurricane Ivan studies regardless of the model physical parameterization choice. Grid spacing was also hypothesized to impact the simulated TC.

intensity with the expectation that simulations with smaller grid spacing would produce more intense TCs based on the results of previous studies. Simulated TC intensity is found to be highly sensitive to model grid spacing in experiments with Hurricane Ivan or with an idealized initial vortex. Simulations using 4 km grid spacing were able to produce TCs that exceeded the MPI of the idealized environment.

A Comprehensive Sensitivity Analysis of the Weather Research and Forecasting Modeling System Over Southern Ontario, Canada Md Mostofa Kamal, 2017

Every year weather events cause billions of dollars property damage and take many lives globally. Preventing as much damage as possible is crucial and one way to help is through having the most accurate advance warning of extreme weather events. Therefore this thesis investigates the sensitivity of precipitation, temperatures and surface energy fluxes i.e. sensible heat flux (SHF), latent heat flux (LHF) and ground heat flux (GHF) in four cumulus cloud (CU), five cloud microphysics (MP) and four planetary boundary layer (PBL) parameterization schemes over five years (2002, 2007, 2008, 2014 and 2015) with significantly different climatological atmospheric conditions, horizontal grid spacing, two seasons (winter and summer) and feedback between the nest and its parent domain using the dynamical downscaling technique of the Weather Research and Forecasting (WRF) model. The main objectives are 1) to identify a combination of physics schemes that realistically reproduce observed atmospheric conditions and 2) to improve current understanding of factors influencing the micro climate of southern Ontario, a region of complex land water atmosphere interactions. Ontario is also the most populous province and the largest manufacturing hub of Canada. WRF simulated precipitation and temperature agree well with DAYMET model gridded observations with correlation coefficients of nearly 0.3 to 0.8 and 0.9 respectively. Precipitation showed an average systematic bias for July of 50 to 30 mm and for January of 10 to 30 mm. The simulated precipitation was more sensitive to CU and PBL schemes. WRF simulated temperatures showed good reproducing skill with biases within the range of 1.0 C to 1.0 C in most parts of the domain. Model predicted temperature was quite sensitive to PBL and MP schemes. Model simulated precipitation variability increased when the horizontal grid resolution was refined from 8.0 to 2.67 km. However simulated temperature variability decreased. Overall the model performed better in the 2.67 km resolution simulation than in the highest resolution simulations with grid spacing of 0.888 km, an unexpected finding that suggests the need for carefully designed high resolution dynamical downscaling experiments. WRF's limitation to capture all variation that may occur at a resolution of 1 km, particularly of precipitation in mountainous areas, may result from uncertainties in our understanding of the climate and our inability to parameterize sub-grid scale processes realistically. WRF reproduced the diurnal variability of the SHF very well but systematically overestimated LHF compared to eddy covariance (EC) tower measurements for June of 2007 and 2008. For the interior of all three domains in July 2002, spatial distribution was overestimated for SHF and underestimated for LHF with biases ranging from 30 to 30 W m² over most of the area when compared to the North America Land Data Assimilation System (NLDAS) model gridded analysis. WRF showed little sensitivity to the choice of PBL scheme except for January 2002's LHF, the hottest

January of the five studied. If forced with distinctively different annual climatological boundary conditions such as extreme cold in January 2014 and below average temperatures in January 2015, the model's simulated spatial distribution of energy flux bias indicates behavior that clearly differs from NLDAS analysis. A large energy flux bias occurs over the smaller shallow northern lakes, perhaps due to incorrect representation of their water temperatures. Overall, the Kain-Fritsch KF-CU, Yonsei University YSU-PBL, and WRF Single Moment 6-class WSM6 microphysics parameterization schemes exhibit superior results over the domain studied. The WRF model shows a high skill score over southern Ontario while reproducing observed climate means and statistics. Nevertheless, the model's performance depends on the meteorological variables, season, and synoptic conditions. The Great Lakes strongly influence atmospheric conditions in southern Ontario by affecting precipitation and surface temperatures ranging from the diurnal to the seasonal timescales. These results affirm the need for extensive sensitivity analysis for both research and operational applications. However, the findings are limited by the shorter spin-up time and by having only one month simulation, although WRF ran for a month in both the winter and summer over multiple years.

Impacts of Physical Parameterization Schemes and Soil Moisture Initialization on Boundary Layer Evolution in the Weather Research and Forecasting (WRF) Model Grace M. Cutting, 2022. Numerical weather prediction NWP models have become a necessary addition to the atmospheric research community over the last several decades, and atmospheric modeling has been used internationally for numerous operational and research purposes. NWP models contain a vast number of combinations of physical and dynamical parameterization schemes; however, they are not always accurate in forecasting weather phenomena at a particular location, as different combinations of parameterization schemes represent differing conditions. Weather Research and Forecasting WRF model simulations were run to explore which of the commonly used planetary boundary layer (PBL) schemes best represented upper air data as well as PBL evolution over northeastern Colorado, southeastern Wyoming, southwestern Nebraska, and northwestern Kansas. Additionally, errors in soil moisture initialization were investigated to determine if there was an impact on boundary layer evolution. Based on model soundings, the Grenier-Bretherton-McCaa-GBM scheme was the most representative of this region in terms of the overall PBL structure, and there was no evidence to suggest that errors in soil moisture initialization impacted boundary layer evolution, but rather the choice in surface layer scheme tended to influence the modeled boundary layer when paired with specific PBL schemes.

Modeling the Sensitivity of the February 22-23, 2017 Winter Storm to Microphysics Parameterization and Microphysics Processes Over Colorado and Wyoming Ethan Collins, 2019. Accurate weather forecasts are crucial to the profitability of industry in the United States, such as the transportation of goods across the country via semi-trailer trucks, air travel, recreation activities, etc. This topic is of particular concern over the state of Wyoming, as wintertime weather forecasts are often prone to error. Wyoming not only has a sparse network of surface and upper air observations but also complex terrain that cannot be properly represented in regional numerical models. Model forecast errors can have a substantial

impact on the ability to issue advisories and close highways if necessary We focus on improving our understanding of why regional numerical weather prediction NWP models often fall short of predicting accurate snow totals via a case study of an event that occurred on February 22 24 2017 High resolution simulations are run using the Weather Research and Forecasting WRF model Four different microphysics parameterizations are utilized in this study Thompson Morrison two moment Predicted Particle Properties P3 and the WRF Single Moment 6 Class Scheme The coupling between cloud properties and radiation as well as the role of latent heat release due to individual microphysical processes are also explored The simulated precipitation is compared with both Snow Telemetry SNOTEL and Parameter elevation Relationships on Independent Slopes Model PRISM to quantify model errors and improvements using higher resolution simulations and advanced microphysical parameterizations The results support past studies that suggest a dependency exists regarding the choice of microphysics parameterization and resolution over this region All of the parameterizations utilized in this study overpredict snowfall accumulation no clear bias as a function of altitude is identified The coupling between the cloud microphysics and radiation is also found to have a minimal impact on storm strength storm track and snowfall amounts Lastly certain microphysical processes and the resultant latent heating are found to affect the storm characteristics No cooling due to sublimation and no warming due to deposition have the largest influences on snowfall accumulation and cyclone track No cooling due to sublimation was found to decrease negative buoyancy production resulting in deeper clouds and more snowfall accumulation While no warming due to deposition was found to reduce buoyancy production deeper clouds and thus less snowfall accumulation Furthermore reducing ice fall speeds by 50 % was found to increase snowfall accumulation while increasing ice fall speeds by 50 % was found to decrease snowfall accumulation
